Abstract

In resource management, the kind and extent of ecological co-occurrence between closely related species frequently requires assessment of the spatial relationship among taxa. In my study, analysis of inter-species pair-wise distances revealed no syntopic overlap between Church's sideband (*Monadenia churchi*) and Trinity bristle snails (*M. setosa*). No pair of samples had the same geographic coordinates and no parapatric boundary in environmental covariates was evident between species. This "microsympatric" spatial relationship resembled a metapopulation structure with no high degree of overlap, as co-occurrence was rare and small in geographic scope. Fifteen forest cover-types and 82 soil-types were identified between species. The most common forest-type for *M. churchi* was Sierra Mixed Conifer (39.9%) and Douglas fir (28.9%). In *M. setosa* the most common forest-types were the same but in much different percentages (78.8% and 14.8%, respectively). Sixty-one and 39 soil-types were associated with samples of *M. churchi* and *M. setosa*, respectively. The Hohmann-Neuns family complex was the most common (22.5%) soil-type for *M. churchi* and the Holland Deep-Hugo family complex was the most (50.6%) dominant for *M. setosa*. There were significant differences between species in all environmental attributes and in values of monthly temperature and precipitation, which reflected variance in the mesoclimatic regime seasonally. Principal Components Analysis (PCA) accounted for 57.8% of the dispersion contained in environmental variables on the first 3-eigenvectors. Evapotranspiration and Summer and Winter Temperatures loaded positively while Summer and Winter Precipitation and Elevation loaded negatively along PC I (26.2%). Given significant inter-species differences in ecological occupancy, it seems plausible that microsympatry is based in part on both mesoscale habitat variance and subtle differences in mesoclimate defined by seasonal variation in temperature and precipitation. The hypothesis that *M. setosa* is adapted to cool habitats and *M. churchi*

to warmer more arid environs in microsympatry was substantiated at a macroscale level.

Key words: co-occurrence, ecological assessment, land snail, microsympatric, *Monadenia churchi*, *Monadenia setosa*, sympatric, syntopic, temperature regime

Introduction

Sympatry is a term used to describe species that occur in the same place at the same time with overlapping geographic ranges. This relationship may include the same local community such that they are close enough to interact (i.e., microsympatry; Jorgensen and Fath 2008).

In contrast, parapatry describes a situation where geographically separated ranges of closely related species abut along a common boundary as a function of spatial changes in environmental factors (Anderson and Evensen 1978; Bull 1991; King 1993), which define species-specific habitats across their parapatric boundary. Alternatively, the term “syntopy” is used to describe individuals of different species that occur side-by-side in nature, using the same habitats. Historically, a primary goal of community ecology has focused on discerning what factors drive the distribution and associated spatial relationships of species that occur in both sympatry and allopatry. The study of sympatry, particularly in populations of closely related species (i.e., sister taxa), has contributed to many important and contentious ideas in ecology and evolutionary biology (Jorgensen and Fath 2008). Several factors may influence the ecological and spatial relationships among species. Such factors may include abiotic conditions and/or biotic interactions. Knowledge of how these factors influence the distribution of animal communities is central to understanding the ecological and spatial relationships among co-occurring taxa (Soberón 2007; Heart et al. 2018).

In northern California, terrestrial snails are widely distributed within forest and woodland ecosystems. Church's sideband snail (*Monadenia churchi*) and the Trinity bristle snail (*M. setosa*) have coincident spatial distributions in a small area within the south-central portion of the Greater Trinity Basin ([Fig. 1](#)). The geographic distribution of *M. setosa* includes the Klamath Bioregion centered on the southwestern edge of the Greater Trinity Basin watershed (Sullivan 2021). In comparison, the range of *M. churchi* encompasses virtually the entire Greater Trinity Basin, including areas outside the basin south to the northern extent of North Coast Bioregion and east to the Sacramento River Valley at the edge of the Sierra Nevada escarpment ([Fig. 1](#)). Taxonomically, the geographic distribution of *M. setosa* lies on the eastern edge of the subgenus *Monadenia*, whereas the range of *M. churchi* belongs to the inland subgenus *Shastelix* (Roth 1981; Roth and Sadeghian 2006). These subgeneric relationships appear reflected in a recent phylogenetic analysis (Sullivan 2021) summarizing geographic variation within riverine-segregated populations of *M. setosa*, where *M. churchi* and *M. mormonum* (Sierra sideband) were hypothesized to be sister species to *M. infumata* subcarinate (Redwood sideband), *M. ochromphalus* (yellow-based sideband), and *M. setosa*.

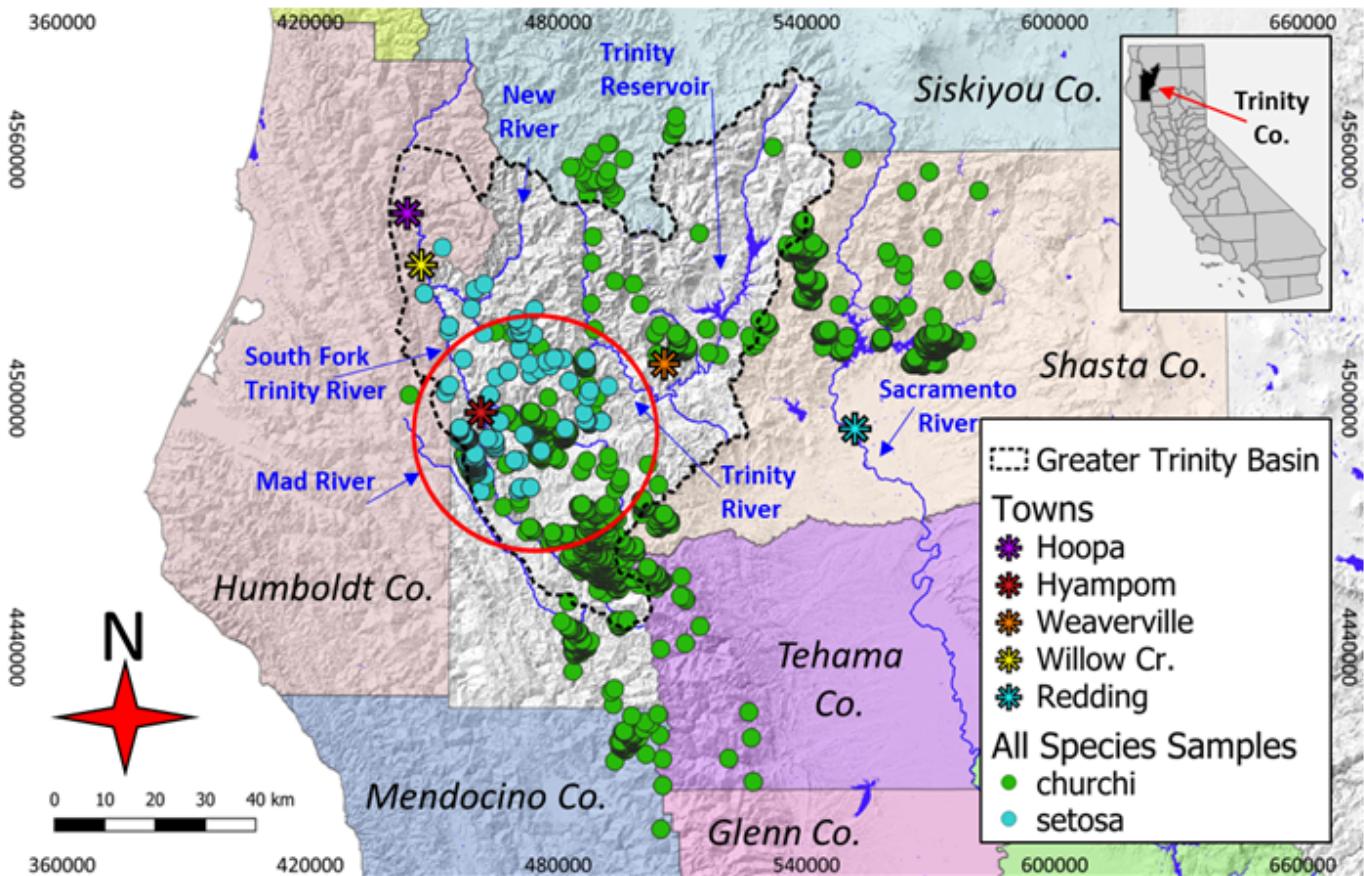

Figure 1. Map of study area and distribution of sampled populations of *M. churchi* and *M. setosa* within the Greater Trinity Basin, including the area of hypothesized co-occurrence (i.e., red circle). Included is a red colored buffer outline (radius ~20 km = 1,256.6 km² area) surrounding the hypothesized center of co-occurrence.

Although co-occurrence and qualitative habitat differences between *M. churchi* and *M. setosa* were highlighted early on (Hanna and Smith 1933; Roth 1978), the ecological preference and degree to which these two taxa segregate spatially is yet unclear and has never been quantified in multidimensional space. For example, Hanna and Smith 1933 noted that *M. setosa* was absent at many localities within the eastern more arid portions of the range of *M. churchi*, even though these situations appeared ecologically “analogous.” Surveys for *M. setosa* along tributaries of Hayfork Creek, entering the Hayfork Valley from the southeast, produced *M. churchi* but no *M. setosa* (Hanna and Smith 1933; Roth and Pressley 1986). This area is located at the eastern edge of the range of *M. churchi* (Fig. 1) and is characteristically drier in overall climate and vegetation diversity relative to more northern and western habitat typical of *M. setosa*. As a result of this earlier work and follow-on surveys, Roth (1981) and Roth and Pressley (1986) hypothesized that *M. churchi* is better adapted than *M. setosa* to more xeric and elevated temperature regimes. Whereas *M. setosa* may be competitively superior in riparian woodland situations to the exclusion of *M. churchi*. Moreover, considering thermal metrics, the subgenera *Monadenia* and *Shastelix* show little overlap (Roth 1981). Nonetheless, we have only a limited understanding of the factors that govern the co-occurring distribution of these two species as relates to landscape-level environmental gradients.

Here, I use pair-wise inter-specific distance values based on geographic coordinates, macroscale GIS-based environmental data, and seasonal (i.e., monthly) variance in mesoscale climatic attributes to assess how these two species co-exist spatially and macroecologically within the area of co-occurrence based on determined presence. Together, my analyses quantify the extent of co-occurrence and help us

understand how these two species co-exist ecologically, what factors influence their co-occurrence, and whether there is clear evidence for sympatry, parapatry, or syntopy in the region of overlap.

Methods

Study Area and Species Distribution

My study focused on that segment of the Klamath Bioregion centered on the Greater Trinity Basin watershed, which includes Humboldt, Mendocino, Shasta, Siskiyou, Tehama, and Trinity counties, and much of the Shasta-Trinity and Six Rivers National forests ([Fig. 1](#)). Importantly, this area is also bisected by several major river systems and associated tributaries. Within this biogeographic zone there are abundant forest cover types: Klamath montane and Douglas fir (*Pseudotsuga menziesii*), white fir (*Abies concolor*), ponderosa pine (*Pinus ponderosa*), sugar pine (*P. lambertiana*), incense cedar (*Calocedrus decurrens*), tanoak (*Notholithocarpus densiflorus*), and Pacific madrone (*Arbutus menziesii*; Sullivan 2022c). At its southwest boundary this segment of the basin also intergrades with montane coastal forest of the North Coast Bioregion (Welsh 1994).

Basin watersheds are mostly within mountainous terrain, with the only level land in a few “narrow” valleys (i.e., Weaverville Basin, and Hyampom and Hayfork valleys) dominated by mixed conifer and hardwood forest, riparian corridors of white alder (*Alnus rhombifolia*), big leaf maple (*Acer macrophyllum*), dogwood (*Cornus* sp.), and various species of willow (*Salix* spp.). Basin uplands consist of deciduous hardwood understories of Pacific madrone, giant chinquapin (*Chrysolepis chrysophylla*), tanoak, and canyon live oak (*Quercus chrysolepis*) cover-types as far south as Mendocino County. Along the foothills of the western slope of the Sacramento River Valley major forest cover and vegetation-types proceed downslope in decreasing elevation through Klamath mixed conifer forest, patches of montane hardwoods and progressively tapering riparian corridors, montane and mixed assemblages of chaparral, and annual grassland (Munz and Keck 1959; Roth and Eng 1980).

Populations of *M. churchi* are described as inhabiting many of same forest cover-type conditions described for *M. setosa*, but they are generally linked with open stands and exposed slopes, limestone outcrops, caves, talus slides, lava rockslides, and riparian corridors with deciduous understory associated with nearby forest debris in heavy shade ([Fig. 2A](#); Roth 1981). Many sites around Shasta Lake consist of remnant shrub associations, various species of buck brush (*Ceanothus* sp.), manzanita (*Arctostaphylos manzanita*), and pine-oak woodland (Hanna and Smith 1933). Conversely, populations of *M. setosa* are typically found within mesic montane and mixed conifer-hardwood forests and riparian corridors, and occasionally upland environs dominated by sclerophyllous deciduous hardwood understories ([Fig. 2B](#); Sullivan 2021a, b).

Figure 2. A) Primary external characteristics and examples of typical microhabitat found for each species. In *M. setosa* adult shells are large sized (25.2–35.0 mm in diameter) with a low spire and cone of ~6.5 whorls. The coloration and pattern of banding is generally uniformly dark chestnut brown. Periphery of shell with a dark brown band (~2 mm wide) below which is a band ranging from ochre to umber (~2 mm in width). Periostracum covering bears distinct short translucent bristles on both ventral and dorsal

surfaces. Density of bristles covering dorsal surface of shell varies from dense to sparse. B) In *M. churchi* adult shells are medium sized (17.8–23.5 mm in diameter). The spire is a somewhat low even cone with 5.25 whorls that are evenly rounded. The coloration and pattern of banding is generally uniformly pale brown. The periphery of shell with a darker brown band than rest of shell that is bounded above and below by light cream-colored bands. At some locations (e.g., around Shasta Lake) the shell may be considerably darker brown. Thin periostracum skin is devoid of distinct bristles on both the dorsal and ventral sides. Size and thickness of the shell, and presence of distinct bristles in adults immediately separates *M. setosa* from *M. churchi*.

Survey Methods and Data Collection

I derived predictor variables to assess geographic variation in co-occurring samples of *M. setosa* and *M. churchi* using Landsat Visual Ecological Groupings of vegetation-types (i.e., CALVEG; USFS 1981) and California Wildlife Habitat Relationships (CWHR; Airola 1988; Mayer and Laudenslayer 1988; Goodchild et al. 1991; Sawyer and Keeler-Wolfe 1995; Garrison et al. 2002). GIS-based CWHR layers provided information on forest stand structure at a ~16.2-ha minimum mapping unit; and a minimum mapping size of ~2.5-ha pixels was used to contrast environmental variables associated with each sample site. I used 18 environmental predictor variables including a seasonal component of environmental variance (mean monthly minimum and maximum temperature and mean monthly precipitation; [Table 1](#)) to evaluate macroscale habitat relationships between species. From these variables I created four sets of covariate categories: 1) Forest Cover Type [CWHR]; 2) Forest Stand Structure [i.e., CALVEG]; 3) Mesoscale Climate (geo-rectified raster data, PRISM Climate Group [2023]; Daly et al. 2008); and 4) Exposure-Distance to Nearest Stream (henceforth referred to as Exposure-Distance), to describe attributes of the landscape (scale = 10-m digital elevation models). I used Inverse Distance Weighting (IDW; GISGeography 2023) to produce deterministic multivariate geographic interpolation maps from a scattered set of points depicting variance in summer and winter precipitation and temperature across the co-occupied species landscape (QGIS Development Team 2021).

Table 1. Categories and individual biotic and abiotic environmental variables, classification codes, and plant species assemblages used to compare macroscale variance between samples of co-occurring samples of *M. churchi* and *M. setosa*.

Predictor variable	Description
1. Cover-type	CWHR Forest Stand Vegetation Cover-Types: AGS = Annual grassland, BAR = Barren, BOP = Blue oak-foothill pine, CPC = Closed-cone pine cypress, DFR = Douglas fir, JPN = Jeffrey Pine, Ponderosa Pine, Sugar Pine, KMC = Klamath mixed conifer, MCH = Mixed chaparral, MCP = Montane chaparral, MHC = Montane hardwood conifer, MHW = Montane hardwood , PPN = Ponderosa pine, SCN = Subalpine conifer, SMC = Sierran mixed conifer, WFR = White fir.

Predictor variable	Description
2. Conifer Cover from above (CCFA) 3. Hardwood cover from above (HCFA) 4. Over-story Tree Diameter (OSTD) 5. Total Tree cover from above (TCFA) 6. Tree Size Class (TSIZ) 7. Soil-type (MUSYM)	<p>Forest Stand Attributes: CALVEG vegetation cover from above (mapped vegetation [%] cover [crown] from above) as delineated by aerial photos. Total tree cover from above, conifer tree cover from above, and hardwood cover from above were mapped as a function of canopy closure in 10% cover classes: 0 (< 1%), 5 (1-9%), 15 (10-19%), 25 (20-29%), 35 (30-39%), 45 (40-49%), 55 (50-59%), 65 (60-69%), 75 (70-79%), 85 (80-89%), and 85 (90-100%). CALVEG overstory tree diameter class mapped over-story tree diameter class of mixed tree types using average diameter at breast height (DBH = 1.37 m above ground) for trees forming the uppermost canopy layer (Helms 1998) using average basal area (Quadratic Average Diameter or QMD; Curtis and Marshall 2000) of top tree story categories: 1 = seedlings (0-2.3 cm QMD), 2 = saplings (2.5-12.5 cm QMD), 3 = poles (12.7-25.2 cm QMD), 4 = medium sized trees (50.8-76.0 cm QMD), and 5 = large sized trees (> 76.2 cm QMD). Tree size classification derived from mapped attributes corresponding to parameters derived from the CALVEG and CWHR systems. Tree size codes (ranked): 1 = seedling tree, 2 = sapling tree, 3 = pole tree, 4 = small tree, 5 = medium-large tree, and 6 = multilayered tree. Specific soil-types were derived from USDA-NCSS soil survey data (SSURGO 2023) and verified regionally by use of the University of California U.C. Davis Soil Research Lab (UCD 2023).</p>
8. Evapotranspiration (EVAP mm) 9. Summer Temperature (TASM °C) 10. Winter Temperature (TAWN °C) 11. Summer Precipitation (PASM mm) 12. Precipitation (PAWN mm) 13. Minimum Temperature (TMIN1-12 °C) 14. Maximum Temperature (TMAX1-12 °C) 15. Average Precipitation (PPT1-12 mm)	<p>Average Monthly Mesoscale Climatic Attributes Climate attributes were derived from the PRISM (Parameter-elevation Regressions on Independent Slope Model; Daly et al. 1994; Daily et al. 2008), where long-term average datasets were modeled using a spatially gridded digital elevation model (DEM) as the predictor grid for specific climatological periods.</p>

Predictor variable	Description
16. Aspect (ASPC) 17. Elevation (ELEV m) 18. Hill-shade (HLS) 19. Slope (SLOP) 20. Distance to Nearest Stream (DNST m)	Exposure-Distance to Nearest Stream: Maps of aspect, elevation, hill-shade, and slope were all derived from a United States Geological Survey (USGS) Digital Elevation Model (DEM) based on a 1:250,000-scale/3-arc second data resampled to 10-m resolution. Aspect was obtained from a raster surface that identified down-slope direction of maximum rate of change in value from each cell to its neighbors. Equates to slope direction and values of each cell in the output raster show compass direction of surfaces measured clockwise in degrees from zero (due north) to 360° (Burrough and McDonell 1998). Degrees of aspect in relative direction were north (0°), east (90°), south (180°), and west (270°). Values of cells in an aspect dataset indicate direction cell's slope faces. Flat areas having no down slope direction were given a value of -1 in the model. Aspect was quantified by use of aspect degrees binned into one of eight 45° ordinal categories (N, NE, E, SE, etc.). Elevation (m) was obtained from vertical units of a spaced grid with values referenced horizontally to UTM projections referenced to North American Datum NAD 83. Hill-shade was obtained from a shaded relief raster (integer values ranging from 0–255) where the source of illumination was considered infinite. The output raster only considered local illumination angle. Analysis of shadows considered effects of local horizon at each cell. Shadowed raster cells received a value of zero. Slope was obtained from a raster surface that identified gradient or rate of maximum change in z-value from each cell of a raster surface. It relates maximum change in elevation over distance between a cell and its eight neighbors, thus identifying the steepest downhill descent from the cell (Burrough and McDonell 1998). Range of slope values (degrees): flat (0°), steep (35°–45°), moderate (5°–8.5°), to very steep (> 45°). Distance to the nearest stream was obtained from CDFW GIS Clearing house (CDFW 2023).

Statistical Analyses

I performed all statistical tests using R software (R Core Team 2023) and set statistical significance at $\alpha < 0.05$. I evaluated the density distribution (i.e., histograms) of each habitat parameter to the expected theoretical density distributions (i.e., Normal vs. Gamma) using the Akaike's goodness of fit criterion (AIC; Akaike 1973). Although results showed that the frequency distributions of most variables approximated a normal distribution for both species the remainder followed a Gamma distribution ([Appendix I](#); [Appendix II](#)). Additionally, I evaluated univariate normality in macroscale habitat parameters using the adjusted Anderson-Darling test (AD; Razali and Wah 2011) in which all tests for normality failed ([Table S1](#)). Thus, I used nonparametric statistics to evaluate significance in all follow-on tests of environmental parameters for all group comparisons and a Gamma distribution was used for all regressions. I used the Wilcoxon signed rank (V) test with continuity correction to compare the relative percentages of forest-types between species and I used a modified Dunn Test (x^2 , function “dunn.test”, altp = TRUE) to change the output to a two-sided P-value when comparing species with respect environmental attributes (Cross Validated 2023). All nonparametric P-values were adjusted using the Bonferroni correction method ($\alpha = 0.95$) to counteract the problem of inflated Type I errors (Everitt and Hothorn 2011; Josse and Husson 2016).

I used Principal Components Analysis (PCA) modeled for missing data (Josse and Husson 2016) on scaled (i.e., standardized) variables to identify the extent of association among habitat attributes, and to assess the relative ability of each parameter to explain variation between species (Everitt and Hothorn 2011; Sullivan 2022a,b). I tested for significant differences in overall habitat “similarity” based on results of the first three components (i.e., PC I-PC III) between species using permutation-based multivariate analysis of variance (PERMANOVA; package “vegan” function “adonis2”, 1,000 permutations; Oksanen et al. 2013; R Core Team 2023) followed by individual pairwise comparisons of each component by use of the modified Dunn Test. PERMANOVA is a permutation-based technique that makes no distributional assumptions about multivariate normality or homogeneity of variances (Anderson 2017). Because it is based on a distance matrix, PERMANOVA can be applied identically to both univariate and multivariate data. Further, the test statistic is identical to the conventional F-statistic when calculated using Euclidean distance for a single variable (Vicente-Gonzalez and Vicente-Villardon 2021).

I used Generalized Additive Modeling (GAM) in all regressions and a Gamma error-structure to establish the relationship between response variables and the smoothed functions of predictor variables (Wood et al. 2016; Wood 2017). Statistics reported from each GAM included: 1) t-statistic (~significance of smooth lines in the regression) ; 2) Dev.Exp. (proportion of null deviance explained most appropriate for non-normal errors); and 3) P-value plus 95% confidence bands for spline lines (Nychka 1988). In all GAMs I set the base dimension at $k = 3$ degrees of freedom for each smooth line. Spearman’s rank correlation coefficient was used as a follow-on statistic to assess the strength and significance of trends in data delineated by smooth terms (Diankha and Thiaw 2016). I used the “gghdr” package to plot the highest density regions (HDR) of the underlying probability distribution (i.e., 50% to > 99% HDRs) in all regressions. Here, gghdr identified any multimodal relationship between a response and predictor variable in which a credible unobserved parameter interval falls within a particular probability distribution (Hyndman 1996). I performed multiple Spearman correlation analyses (r_s ; 2-tailed test) among the quantitative and ordinal habitat variables to test for potential multicollinearity and evaluate the strength and direction of the relationship between pairs of variables whether linear or not (Corder and Foreman 2014).

Results

Species Intra- and Inter-specific Distances between Co-occurring Samples

My estimate of the potential extent of co-occurrence between *M. churchi* and *M. setosa* was $\sim 1,256.6 \text{ km}^2$ in total area (perimeter = $\sim 125.7 \text{ km}$) based on a minimum spanning polygon surrounding the hypothesized area of overlap ([Fig. 1](#)). As with the known range of both species, I view my estimate of co-occupancy to be conservative pending more extensive sampling in all cardinal directions. PCA of the extent of co-occurrence between species based on geographic coordinates and elevation (i.e., UTM-E, UTM-N, ELEV) showed that variable loadings (i.e., correlations) were high and positive for both UTM coordinates (i.e., 0.773, 0.85) but negative (i.e., -0.882) for elevation along PC I (eigenvalue percentages), which accounted for 72.8% of the total variation along this eigenvector ([Fig. 3A](#)). Topographically, the distribution of co-occurring samples followed primarily a north-west and secondarily a south-east geographic direction that included both sides of the mainstem Trinity and South Fork Trinity Rivers and the headwaters of the upper Mad River. This geographic orientation was clearly illustrated by

the 95% confidence ellipses surrounding samples of each species in 2- dimensional space.

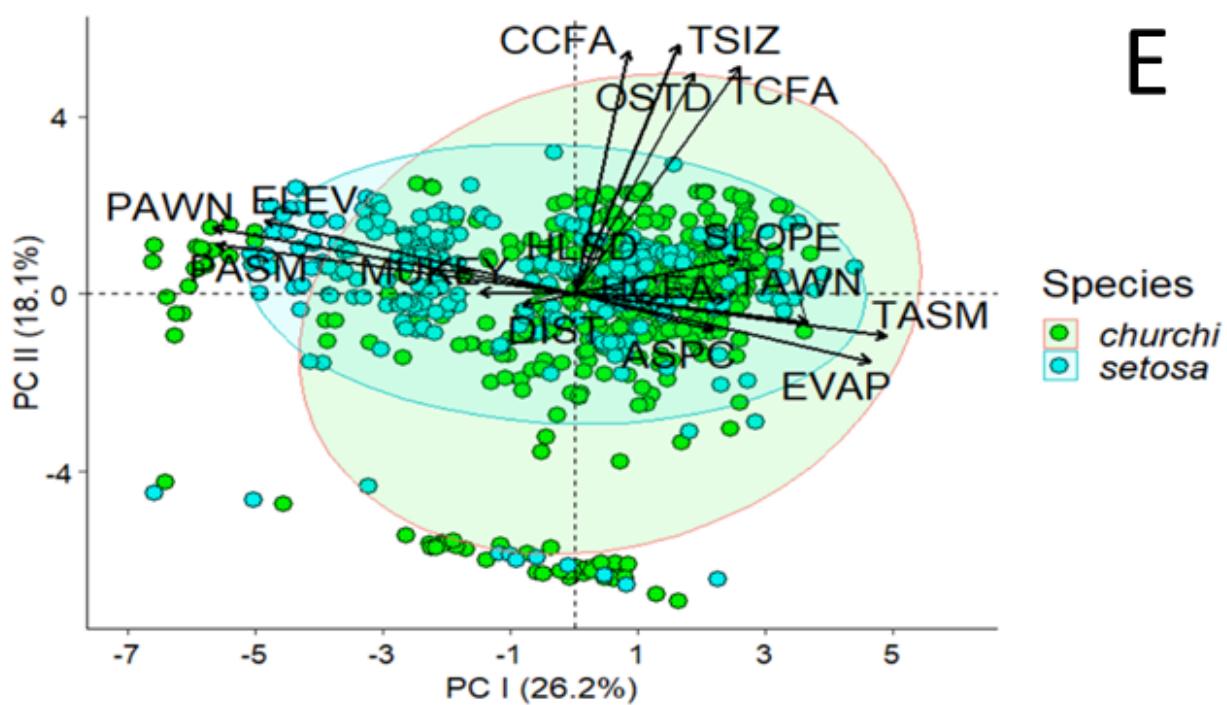

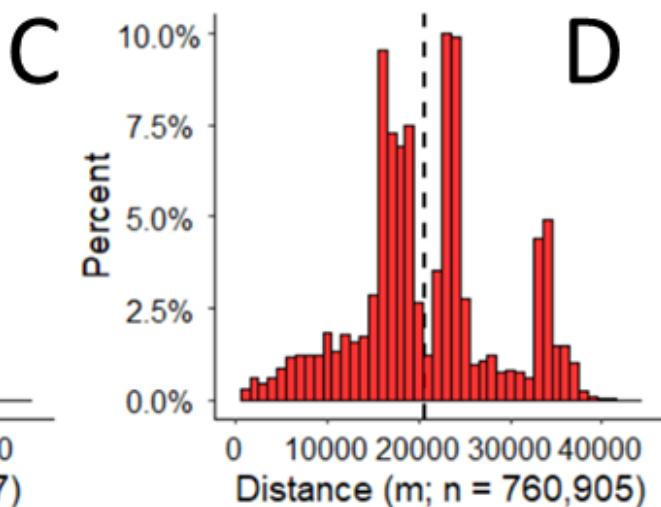

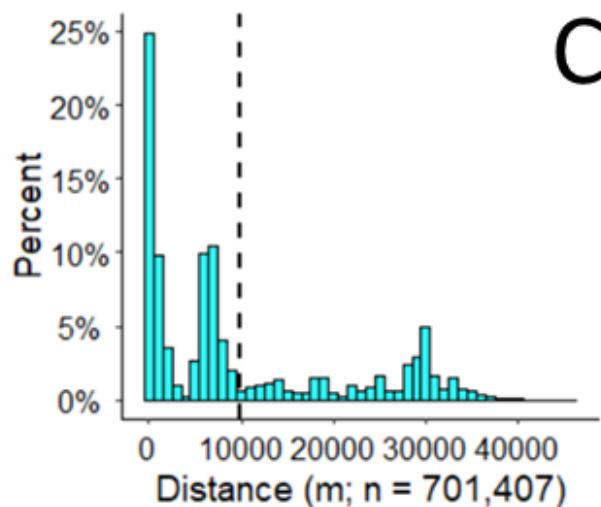

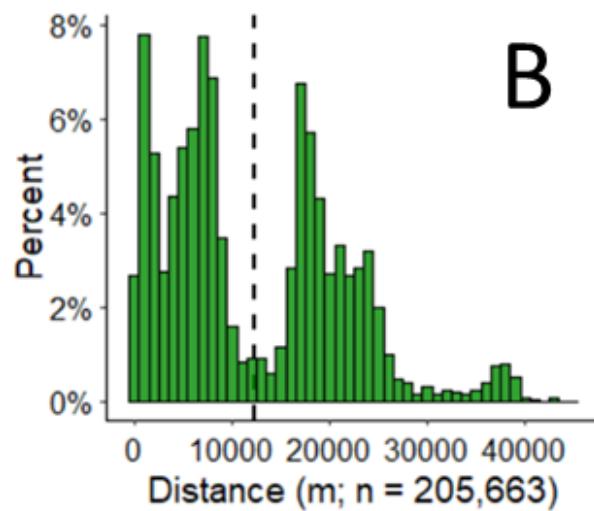

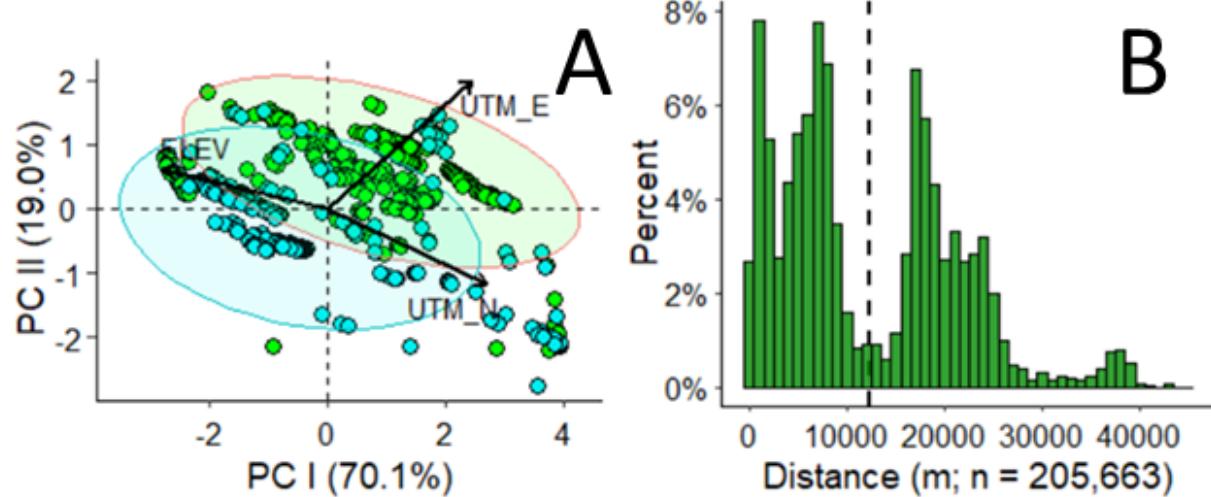

Figure 3. A) Principal Components Analysis (PCA) of co-occurring samples of *M. churchi* and *M. setosa*. Sample locations were based on UTM-east and UTM-north grid coordinates. Percent histogram of QGIS derived pair-wise intra- and inter-species geographic distances (m) between all samples of: B) *M. churchi*, C) *M. setosa*, and D) *M. churchi* vs. *M. setosa*. Data based on UTM coordinates at each species-specific collection site. Mean value = vertical dashed black colored line; n = number of pair-wise distances in each comparison. E) PCA of environmental attributes measured at each site where snails were found. Categories and predictor variables are: 1) Forest Stand Structure: CCFA = Conifer Cover from Above, HCFA = Hardwood Cover from Above, OSTD = Over-story Tree Diameter, TCFA = Total Tree Cover from Above, TSIZ = Tree Size Class, and MUSYM = Soil-type; 2) Mesoscale Climate: EVAP = Evapotranspiration, PASM = Average Annual Summer Precipitation, PAWN = Average Annual Winter Precipitation, TASM = Average Annual Summer Temperature, and TAWN = Average Annual Winter Temperature; and 3) Exposure-Distance: ASPEC = Aspect, DNST = Distance to Nearest Stream (m), ELEV = Elevation, HLSD = Hill-shade, and SLOP = Slope.

Based on UTM coordinates the average distance between samples based on GIS analyses was: 1) *M. churchi*: $\bar{x} = 12.3$ km (min = 0.0 km, max = 45.3 km), 2) *M. setosa*: $\bar{x} = 9.9$ km (min = 0.0 m, max = 45.7 km), and 3) *M. churchi* vs. *M. setosa*: $\bar{x} = 20.7$ km (min = 0.1 km, max = 48.2 km). Similarly, inter-specific minimum pair-wise distances derived from UTM coordinate between samples of *M. churchi* vs. *M. setosa* were considerably larger and much less frequently documented than between samples of only *M. churchi* or samples of only *M. setosa*. For example, there were 1,512 (n = 205,663; **Fig. 3B**) intra-specific pair-wise distances under 200 m for *M. churchi* and 88,546 (n = 701,407; **Fig. 3C**) for *M. setosa*, but only 16 (n = 760,905; **Fig. 3D**) inter-specific pair-wise distances under 200 m for co-occurring (i.e., parapatric) samples and no locations where both taxa had the same UTM coordinates.

Variance in Forest Cover- and Soil-types

In combined samples of both species, I identified a total of 15 CWHR landscape-level (i.e., macroscale) forest cover-types and 82 distinct soil-types. For *M. churchi* the most common forest-type was Sierra Mixed Conifer Forest (SMC = 39.9%) and Douglas Fir Forest (DFR = 28.9%; **Fig. 4A**). In *M. setosa* the forest-types were the same but with very different percentages (i.e., SMC = 78.8% and DFR = 14.8%). Not only did *M. churchi* occur at sites that were more diverse in forest vegetation, but these sites had also much higher minor percentages of Mixed chaparral (MHC = 7.1%), Montane Chaparral (MCP = 5.9%), Klamath mixed conifer (KMC = 4.9%), and White Fir (WFR = 4.2). Paired Spearman signed-rank correlations revealed a significant relationship in the relative proportions of various forest cover-types ($r_s = 0.540$, $P = 0.039$, $n = 15$) at sample sites between species. Similarly, results of paired Wilcoxon signed-rank tests showed a significant difference between taxa in the relative proportions of forest cover ($V = 100$, $P = 0.020$, $n = 15$).

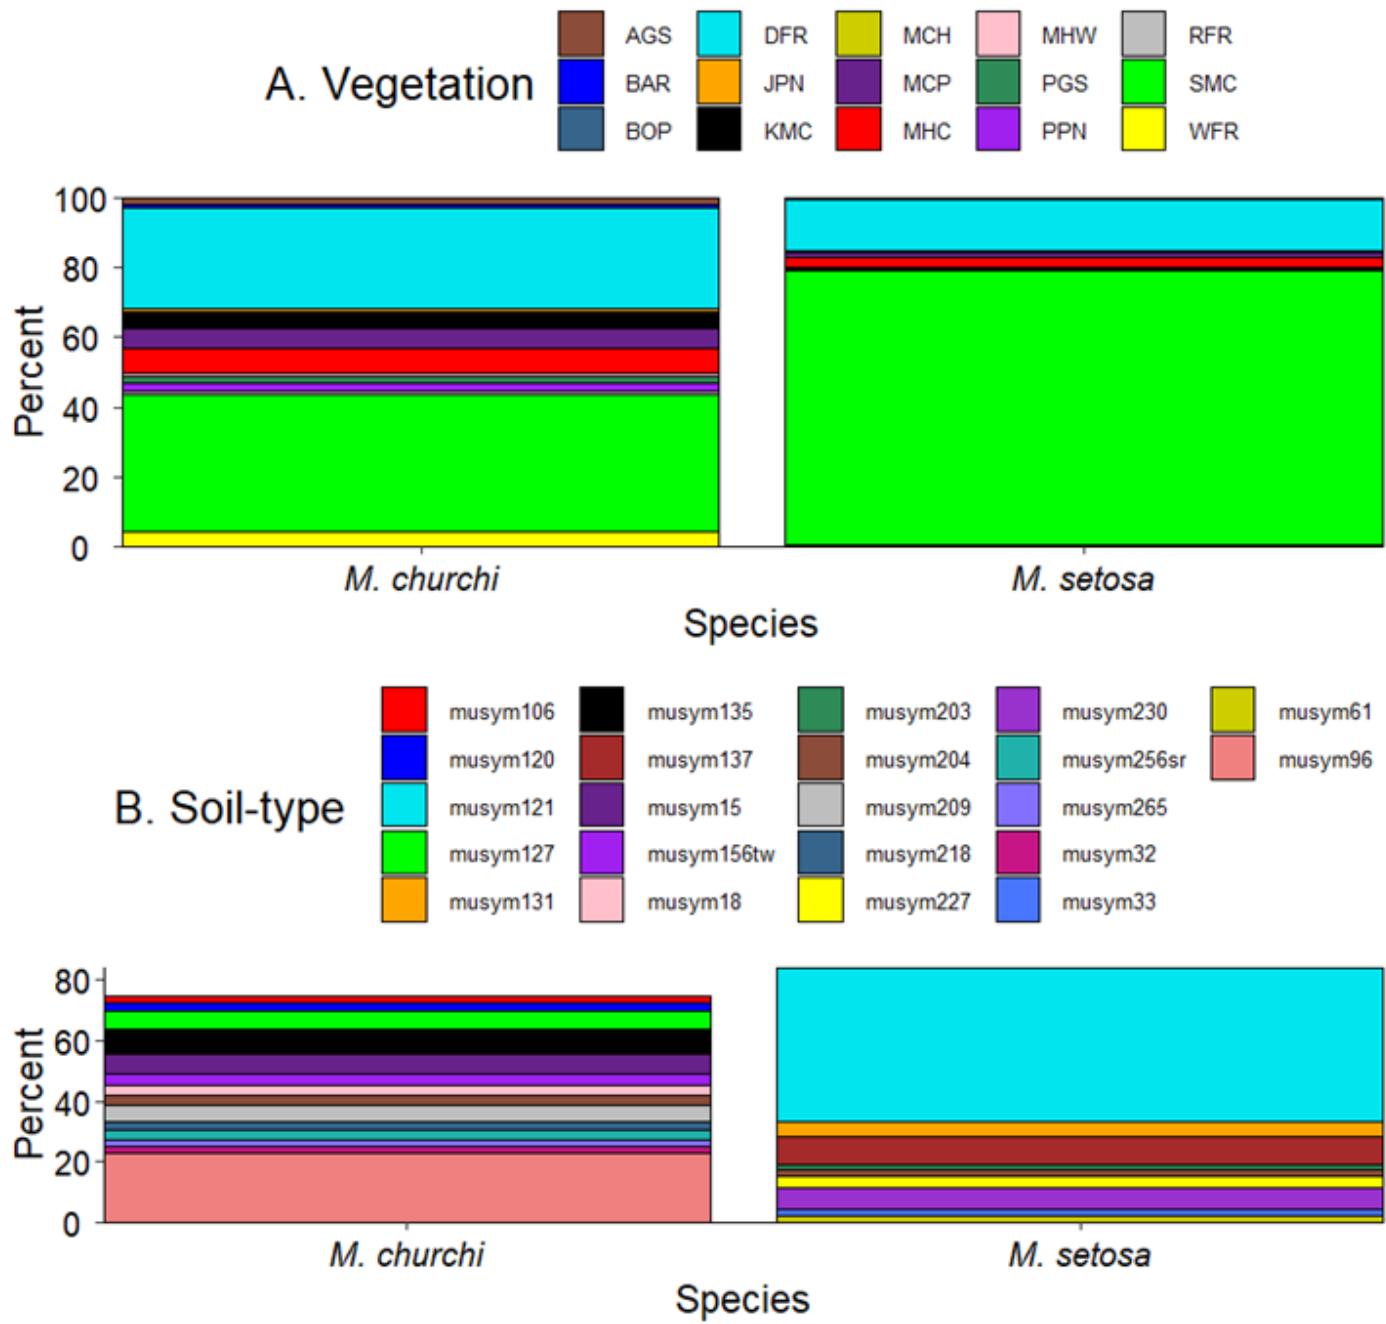

Figure 4. Comparison of A) forest stand vegetative cover-types and B) soil-types found at each species-specific sample. Cover-types: AGS = Annual grassland, BAR = Barren, BOP = Blue oak-foothill pine, DFR = Douglas fir, JPN = Jeffrey Pine, Ponderosa Pine, Sugar Pine, KMC = Klamath mixed conifer, MCH = Mixed chaparral, MCP = Montane chaparral, MHC = Montane hardwood conifer, MHW = Montane hardwood , PGS = Subalpine conifer, PNN = , RFR = Red Fir, SMC = Sierran mixed conifer, and WFR = White fir. Details of specific soil-types are summarized in [Table S4](#).

For soil-type I found 61 and 39 soil-type families associated with samples of *M. churchi* and *M. setosa*, respectively. Proportionally, stacked bar graphs of soil-type families accounting for > 2.0% of the total soil-types showed that samples of *M. churchi* consisted of a far greater diversity of soil-types than did samples of *M. setosa* ([Fig. 4B](#)), with musym96 (Hohmann-Neuns families complex, 40–60% slopes) being the most common (22.5%) soil-type among samples of *M. churchi* and musym121 (Holland, deep-Hugo families complex, 20–40% slopes) being the most dominant (50.6%) soil-type among samples of *M. setosa* ([Table S2](#)). Of these, the only soil-type shared by the two species was musym204 (Neuns family,

60– 80% slopes) at 3.1% for *M. churchi* and 2.1% for *M. setosa*. In soil-type the disparity between species was so great that it was not possible to test for a statistical difference. Further, there also were significant differences between species in all environmental attributes measured at each site and in monthly temperature and precipitation values, which reflected variance in the climatic regime on a season basis ([Table 2](#); [Appendix III](#); [Appendix IV](#)).

Table 2. Non-parametric Dunn's Tests (P-values adjusted using Bonferroni correction) between co-occurring *M. churchi* and *M. setosa* for all environmental variables except monthly temperature and precipitation. Forest Stand Structure (CCFA = Conifer Cover from Above, HCFA = Hardwood Cover from Above, OSTD = Over-story Tree Diameter, TCFA = Total Tree Cover from Above, TSIZ = Tree Size Class, MUSYM = Soil Type); Mesoscale Climate (EVAP = Evapotranspiration, PASM = Average Annual Summer Precipitation, PAWN = Average Annual Winter Precipitation, TASM = Average Annual Summer Temperature, TAWN = Average Annual Winter Temperature; Exposure-Distance (ASPC = Aspect, DNST = Distance to Nearest Stream (m), ELEV = Elevation, HLSD = Hill-shade, SLOPE = Slope. Average Monthly: Minimum and Maximum Temperature (TMIN, TMAN) and Precipitation (PPT).

Environmental Attributes between Species

PCA of all environmental parameters accounted for 57.8% of the dispersion (variance) contained in the data on the first 3-eigenvectors ([Table 3](#)). Vector loadings, direction, and the relationship of each attribute arrow showed that monthly Average Evapotranspiration and Summer and Winter Temperatures had the highest positive loadings along PC I (26.2%; [Fig. 3E](#)). This contrasted sharply with Average Summer and Winter Precipitation, and Elevation, which loaded negatively along PC I. All attributes associated with forest stand structure loaded heavily along PC II (18.1%) except Hardwood Overstory Cover, which was largely typical of *M. churchi* landscapes. Scatter plots of the two PC scores showed the extent of overlap in ecological niche space between the two species. PERMANOVA of factor loadings of individuals showed a significant global difference between species based on the first three components ($F = 213$, $df = 1, 1291$, $P < 0.001$) and post-hoc Dunn's multiple rank sums test showed that each species differed significantly along vectors of multivariate macroscale habitat (PC 1: $\chi^2 = 7.7$, $P < 0.001$; PC 2: $\chi^2 = 5.1$; $P < 0.001$; PC III: $\chi^2 = 17.3$, $P < 0.001$). IDW interpolation maps of geographic variance in seasonal mesoclimate showed that samples of *M. churchi* primarily fell within dryer and slightly cooler topography. Whereas samples of *M. setosa* fell within wetter and slightly warmer areas within co-occupied topography ([Fig. 5A-D](#)) within warmer low elevation more humid riparian tributaries to major river systems throughout the basin ([Table S1](#)).

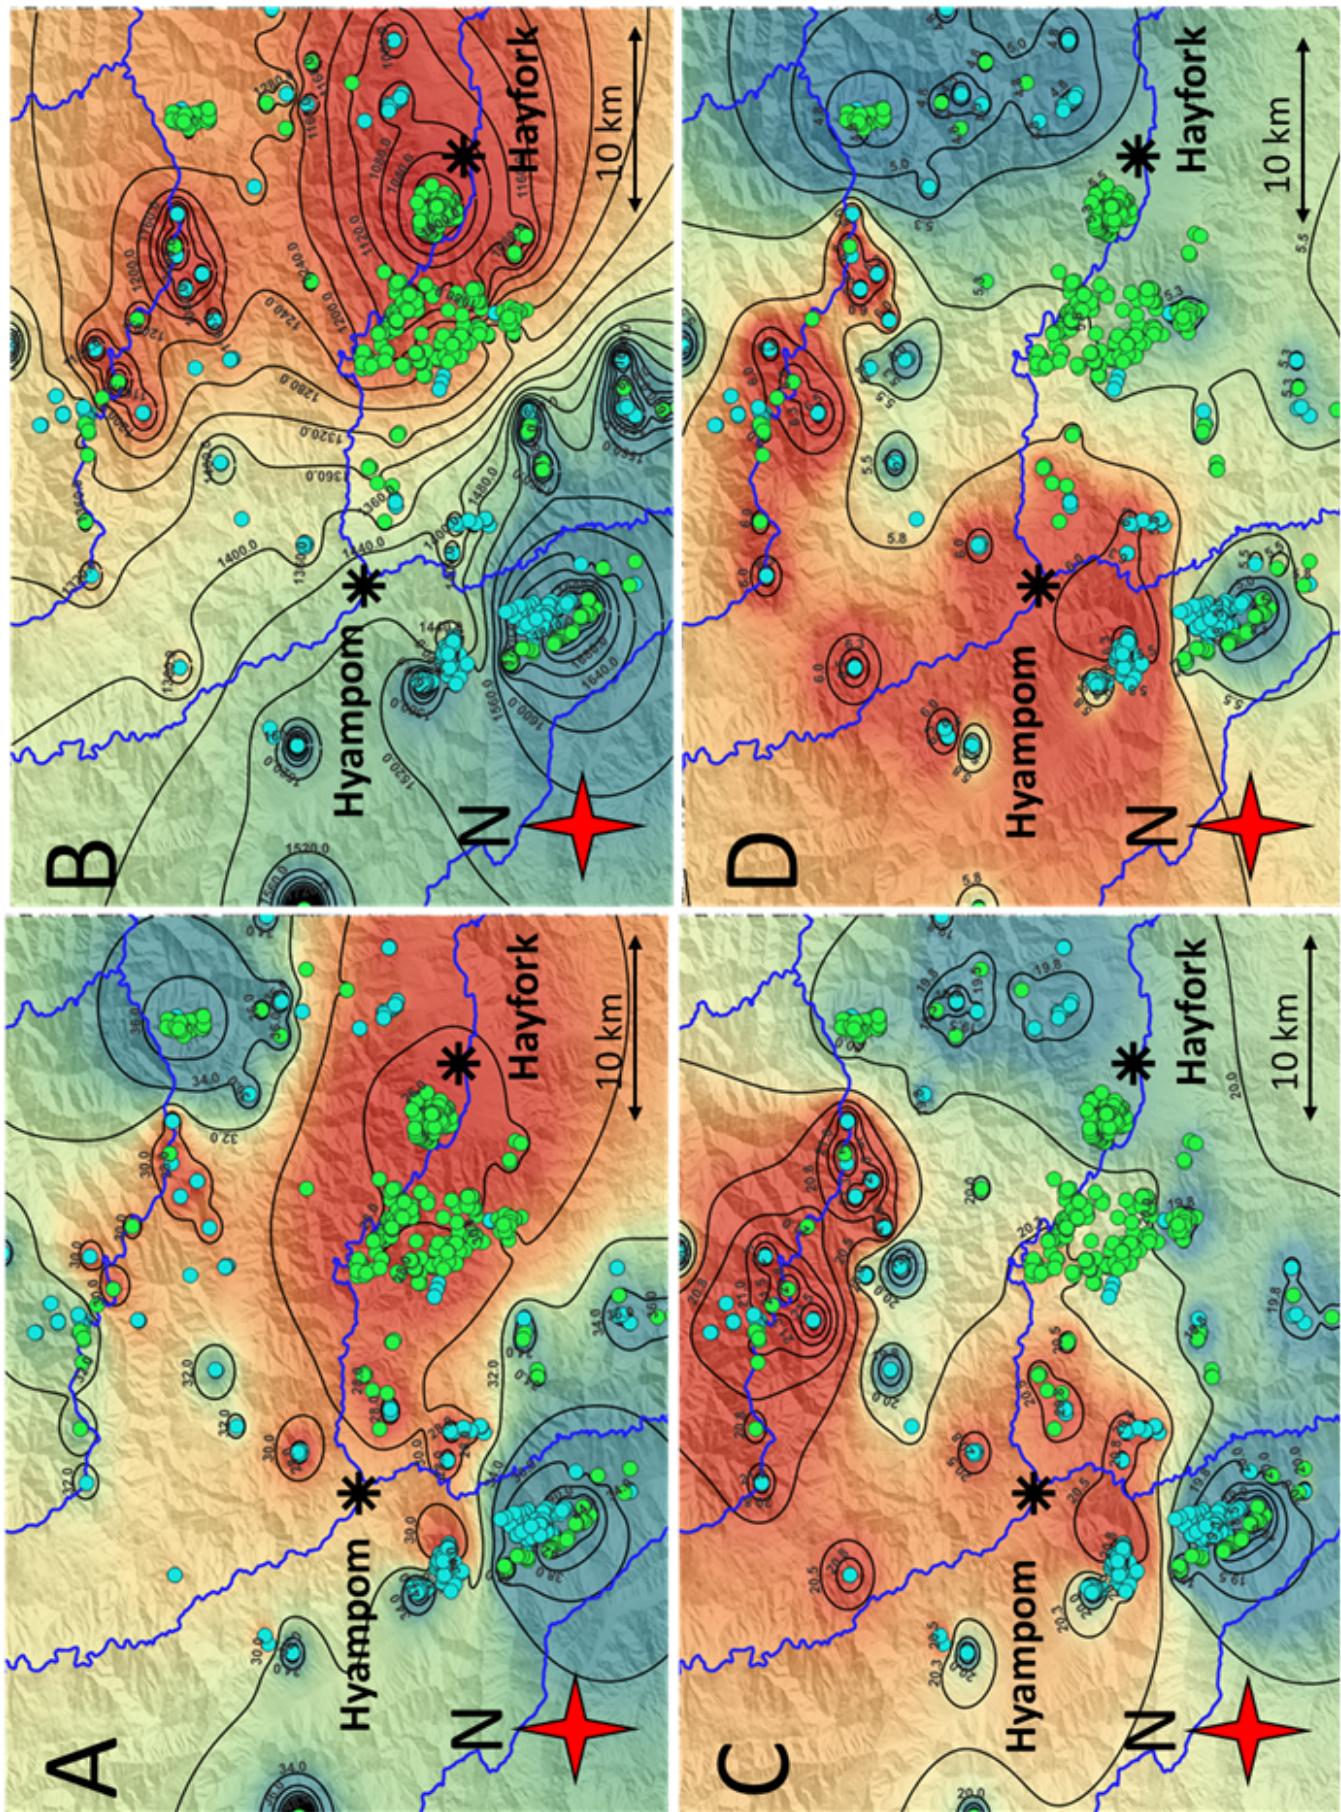

Figure 5. Inverse distance weighted (IDW) interpolation maps of geographic variance in seasonal mesoclimate surrounding the area of co-occurrence. *M. churchi* = green colored points and *M. setosa* = blue colored points. Average: A) summer and B) winter precipitation, and C) Summer and D) winter temperature, including associated contour lines. Areas of higher precipitation and lower temperature are colored blue, and areas of lower precipitation and higher temperature are colored red.

Relationship between Elevation and Distance to Nearest Stream

In the area of co-occurrence, the two species differed significantly in Distance to Nearest Stream ($\chi^2 = 12.2$, df = 1, P < 0.001) and Elevation ($\chi^2 = 13.2$, df = 1, P < 0.001). Average Distance to Nearest Stream for *M. churchi* was 441.1 m (min = 1.1 m, max = 1,147.0 m) and average Elevation was 999.9 m (min = 325.0 m, max = 1,692 m). When compared to samples of *M. setosa* Distance to the Nearest Stream averaged 269.4 m (min = 0.4 m, max = 1,122.2 m) and Elevation averaged 1,136.6 m (318.0 m, max = 1,605.0 m). In both situations Distance to Nearest Stream was substantially smaller and Elevation higher in mesic populations of *M. setosa* than it in samples of *M. churchi*. Although GAM regression of Distance to Nearest Stream vs. Elevation was positive and significant for both taxa ([Fig. 6A,B](#)), correlations between response and predictor variables were not strong in either species (*M. churchi*: $r_s = 0.250$, P < 0.001 and *M. setosa*: $r_s = 0.380$, P < 0.001). Nonetheless, the relationship between Distance to Nearest Stream and Elevation in both species was considerably stronger than between Distance to Nearest Stream and any other macroscale attribute (Tables S3, S4). Examination of HDR's in each GAM showed that in *M. churchi* samples consisted of a large HDR centered at ~500 m from the nearest stream (y-axis) and ~900 m in elevation (x-axis; [Fig. 6A](#)). For *M. setosa* the HDR cluster was much smaller ~1,180 m in Elevation and 200 m from the nearest water source ([Fig. 6B](#)).

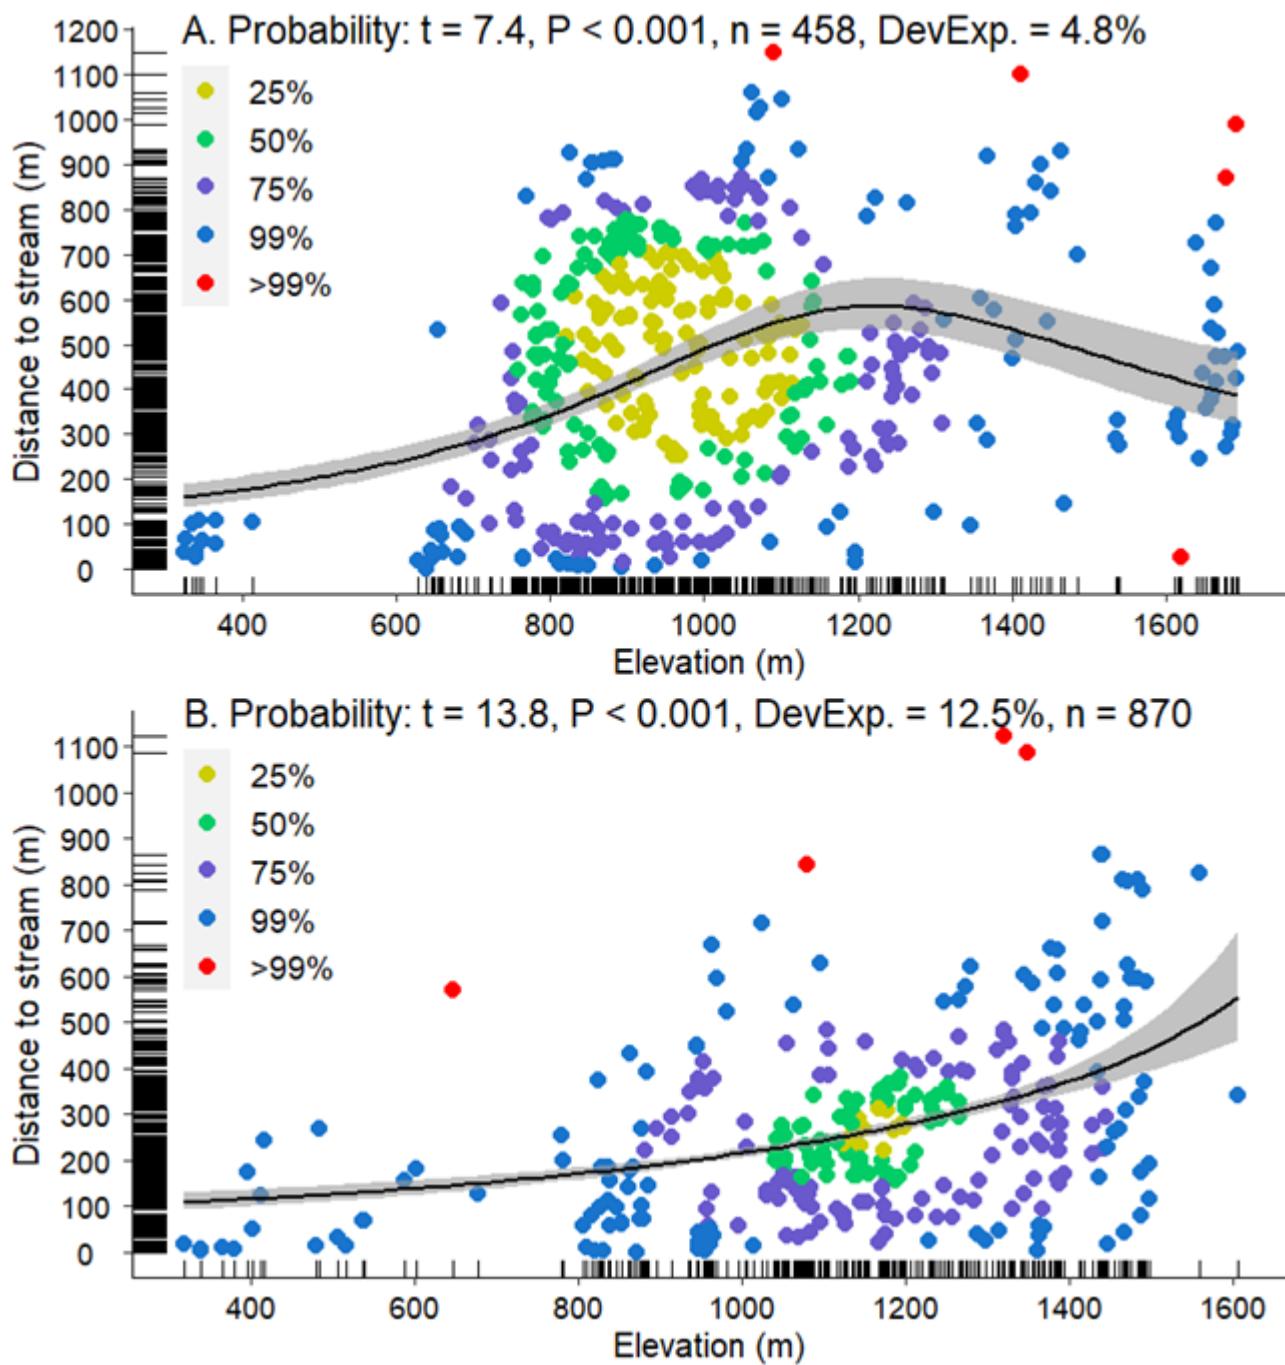

Figure 6. Generalized Additive Modeling (GAM) statistics and plots of highest density regions (HDR) for each regression of Distance to Nearest Stream vs. Elevation for *M. churchi* and *M. setosa* in combination with 50% to > 99% high density probabilities and GAM regression lines surrounded by 95% confidence bands. Rugs (colored black) along both x- and y-axes provide a 1-dimensional display of individual samples.

Discussion

Pair-wise Distance and Co-occurrence

In widely distributed taxa there may, on occasion, be areas where two or more closely related species co-occur. Therefore, it is important to define what kind of co-occurrence between species this spatial

relationship may entail. My study was designed to determine the spatial extent of habitat co-occupancy and importance of macroscale ecological variance in the overlapping geographic distribution of *M. churchi* and *M. setosa*. Analysis of inter-species pair-wise distances based on UTM coordinates showed that there was no overlap in the sample of data I used, which signals that the two species are not syntopic, or parapatric, but “microsympatric.” The finding that Elevation in samples of *M. setosa* was on average higher than in samples of *M. churchi* also indicates lack of syntopy between taxa in relative proximity. Invoking microsympatry between species therefore necessitates quantification of inter-species spacing within the area of co-occurrence, which in each instance will be unique to each pair of species.

Mumladze (2014) concluded that the distinctness of ecological niches at a larger scale (i.e., macrohabitat) than microhabitat patches was not the primary factor in shaping the local spatial pattern of two species of helicoid snails (genus *Helix*) and that other factors (e.g., competition, predation, anthropogenic disturbance, etc.) likely played a more significant role in limiting the local spatial pattern and ecological tolerance of both species. However, I found that ecological variance in co-occurring samples of *M. churchi* and *M. setosa* showed significant differences in macroscale categories of forest-, vegetation-, and soil-type diversity (particularly in *M. churchi*), and continuously distributed environmental variables. Significant differences in mesoscale monthly (i.e., seasonal) precipitation and temperature between species also likely reflect threshold tolerances in regional parameters regulated by variance in thermal and moisture regimes at a landscape level. Similarly, other studies (Gheoca et al. 2021) also suggest that habitat continuity, an arguably macroscale parameter, was the main factor affecting snail abundance and species richness of communities of terrestrial gastropods in riparian forests. As relates to soil-type, no assessments were made at the time surveys were conducted that would allow any detailed understanding of the chemical composition of the soil type(s) associated with each taxon, which would require a microhabitat assessment to determine the nature and significance from a functional physiological perspective.

Thus, in the present example a more detailed proximate-level (i.e., microscale) habitat assessment of the few areas of relative proximity and additional surveys may reveal sites with a heterogenous environment allowing co-occurrence of these two taxa. Future habitat studies in these areas seem warranted because failing to discover *M. churchi* at a site where *M. setosa* is present is only circumstantial evidence that *M. churchi* does not occur there, even though these species have, to date, never been found in syntopy (Roth and Pressley 1986). Inclusive of microsympatric associations with *M. setosa*, *M. churchi* continues its historical biogeographic legacy of inhabiting drier and warmer habitats throughout its geographic distribution as reflected in mean annual temperature and precipitation and seasonal variance in these metrics. Moreover, viability in populations of *M. setosa* continues to be tied to availability of mesic habitat of dense understory shading, temperature- and humidity-regulating conifer and riparian woodlands and scattered stable saxicolous habitat that collectively facilitate long-term survival and reproduction (Roth 1978, 1981; Sullivan 2022b).

Conclusions and Recommendations

Here, I assessed the extent of proximity and similarity in macroscale environmental attributes of *M. churchi* and *M. setosa*. Future inventories in areas of potential co-occurrence previously not surveyed for both species combined with more proximate finer-scale analyses of site-specific microhabitat, above and below ground, focused on thermal and moisture regimes will be required to understand habitat differences for these species (Sullivan 2022b). Identifying critical environmental factors associated with

foraging habitat can also help explain inter-species habitat preferences and provide a baseline for detecting shifts in species distributions based on fluctuating temperature and precipitation regimes effected by regional climate change in future decades. Therefore, understanding the mechanisms by which taxonomically similar species of terrestrial snails co-occur would seem to require: 1) quantification of inter-species spacing at both a macro- and micro-scale, and a detailed exploration of their 2) fundamental niches (i.e., resources and conditions that they could use), 3) realized niches (i.e., resources and conditions that they are using), and 4) behavioral responses to other taxa when in close proximity (Soberón 2007).
